1 Deadlocks

In networking, a deadlock is where transmission of new data ceases due to the system state. A deadlock occurs in this protocol when the last acknowledgement packet from the receiver is lost. The receiver closes after it sends the last acknowledgement packet, so if this packet is lost, the sender thinks that the last data packet was lost and keeps resending the last packet. The sender is thus in a deadlock state: it tries to retransmit the last packet continuously, preventing it from transmitting any more data it may need to.

2 The `magicno` field

The `magicno` field ensures that the message came from this protocol and that some other program has not connected to one of the programs by mistake.

3 Bit errors

Bit errors were solved by adding a checksum to the header. This was calculated when a packet was created by taking the last three digits of the sum of the other header fields. When the sender and receiver received a packet, they calculated what the checksum should be and compared it to the actual checksum. If they were identical, they processed the packet, otherwise they discarded it.

4 The `select()` function

The `select` function, or in Python the `select.select` method, waits until data can be read from the socket (or a timeout, if specified, is exceeded). In channel, this method is used so that it can wait until it can read data from its sockets, and only then read from sockets that have new data. This is useful as it reduces code complexity and prevents the channel program from using CPU resources unnecessarily.

In sender, the `select` method is used to enact the timeout mechanism for re-sending data if an acknowledgement packet isn't received.

5 Verifying correct transferral

To check that the two files were the same, `diff <input_file> <output_file>` was run. This compares the contents of the two files and outputs nothing if they are identical.

6 Packet loss measurement

The number of packets required to send a 512,000-byte file with different packet loss rates was tested experimentally. To do this, the programs were run 10 times for each packet loss rate. The results of this are shown in Table 1 below, and are summarised in Figure 1.

<Explanation goes here>

Table 1 - Number of packets required to send 512,000-byte file for different packet loss probabilities.

Packet Loss Probability	0	0.01	0.05	0.1	0.2	0.3
Packets Sent	134	126	142	162	185	227
	123	136	139	154	191	202
	128	125	138	151	178	272
	122	119	153	131	188	293
	119	130	137	159	167	269
	124	115	141	156	208	269
	124	128	139	147	219	292
	121	123	136	145	173	215
	121	126	142	146	183	274
	118	136	140	150	179	253
Average	123.4	126.4	140.7	150.1	187.1	256.6

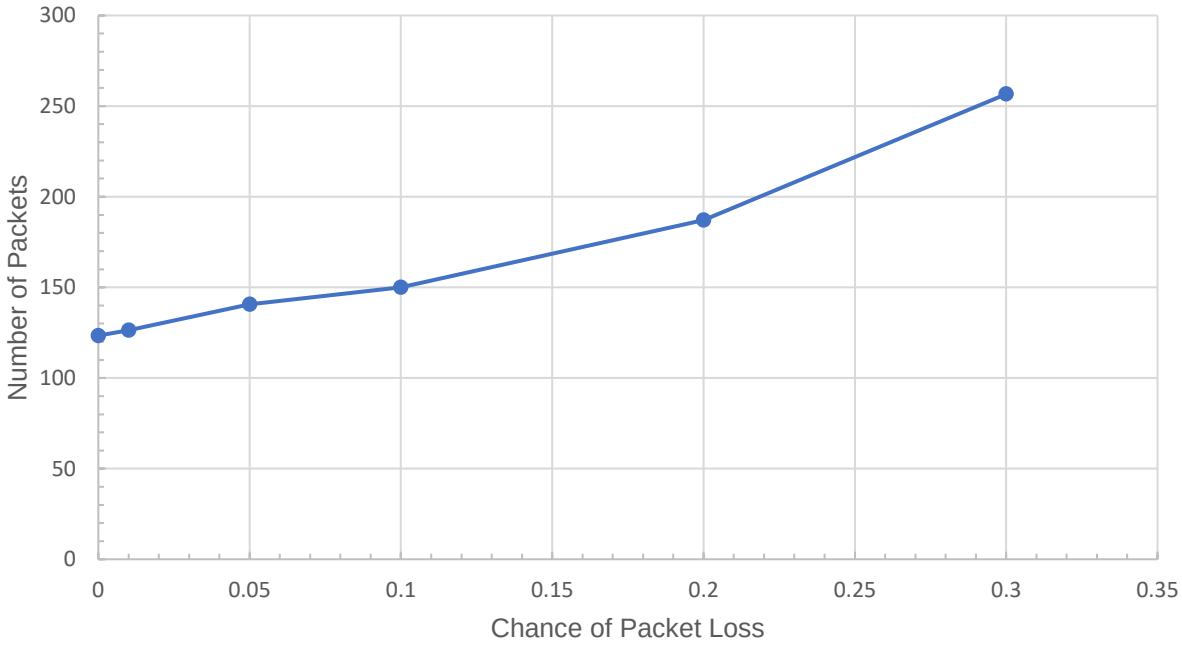

Figure 1 – The average number of packets required to transmit a file 512,000 bytes long.

7 Derivation of average packets required

Let *P* be the probability that a packet is dropped or has its data length field changed, and *N* be the number of packets that is needed to transmit some arbitrary file. Assuming that each transmission is statistically independent of all others, each transmission can be defined as a Bernoulli trial. Let the event the a given packet is dropped be a success and the event that a packet is successfully transmitted be a failure.

If a series of these Bernoulli experiments are performed then the results will have a negative binomial distribution. That is, have a probability mass function of

$$\binom{k+r-1}{k}(1-\gamma)^r\gamma^k, \qquad \text{where } \binom{k+r-1}{k} = \frac{(k+r-1)!}{k!\,(r-1)!} \tag{1}$$

where *k* is the number of successes, *r* is the number of failures, and *γ* is the probability of success. This distribution has the expected value of

$$\mu = \frac{r\gamma}{1-\gamma} \tag{2}$$

where *μ* is the expected value (Pennsylvania State University, 2017), (Weisstein, nd).

The negative binomial distribution measures the number of success before *r* failures occurs. Because of this definition, the average number of packets that must be sent to transmit successfully transmit the file is

$$\mu = N + \frac{N\gamma}{1-\gamma} \tag{3}$$

There should be constant of one as overhead from the protocol - an empty data packet is sent to signal the end of transmission - this packet can be lost and need retransmission. However, this is ignored as the last packet must pass through unmolested for successful transmission to occur.

However, the parameter *γ* is not the same as *P* — it is in fact,

$$\gamma = 2P - P^2 \tag{4}$$

This is because if the acknowledgement packet from receiver is lost then a retransmission also occurs.

Thus, the average number of packets needed to transmit a file that can be split into *N* packets is

$$\mu = N + \frac{N(2P - P^2)}{1 + P^2 - 2P} \tag{5}$$

which can be simplified to

$$\mu = N\left(1 + \frac{P(2-P)}{(P-1)^2}\right) \tag{6}$$

Table 2 shows that the predicted average number of transmissions closely matches the experimental average. The difference will be due to the small sample size of 10 and the fact that the random number generator in Python is only pseudo-random and not truly random.

Table 2 – The predicted average number of packets required to send a 100-packet file compared to an experimental average.

Packet Drop Rate	Predicted Average	Experimental Average
0	123.5	123.4
0.01	126.0	126.4
0.05	136.8	140.7
0.1	152.4	150.1
0.2	192.9	187.1
0.3	252.0	256.6
